ABSTRACT

Seacliff retreat has been variously characterized as the recession rate of the cliff top, of the cliff base, and as the bulk recession rate based on volumetric changes of the entire cliff face. Here, these measures of retreat are compared using nine semi-annual airborne LiDAR (Light Detection And Ranging) surveys of southern California seacliffs. Changes in the cliff base location (where the steeply sloping cliff face intersects the beach) include cliff retreat owing to basal erosion, but also reflect changes in beach sand level and basal talus deposits. Averaged over the 2.5 km alongshore study span, the cliff base actually prograded seaward about 12 cm during the 4-year study. Cliff top change was dominated by few, relatively large (several meters) localized retreats. Cliff face changes, that include failures and deposits anywhere on the cliff profile, had a relatively small mean magnitude compared to cliff top changes and were more widely distributed alongshore. However, the similar alongshore averaged, cumulative cliff top and net bulk cliff face end-point retreat (14 and 19 cm, respectively) suggest that mean cumulative cliff top retreat can potentially be a viable surrogate for mean net cumulative cliff-wide erosion (and vice versa) over relatively short time periods. Cliff face erosion occurred repeatedly at some locations, confirming the presence of seacliff erosion hot-spots during the study period.

1. Introduction

Seacliff retreat, important to coastal management, is often estimated using the recession of the cliff top or cliff base obtained from aerial photographs, topographic maps, or in situ surveys (e.g. Jones and Williams, 1991; Wilcock et al., 1998; Benumof and Griggs, 1999; Moore et al., 1999; Budetta et al., 2000; Hapke and Richmond, 2002; Pierre and Lahousse, 2006; Dornbusch et al., 2008; Greenwood and Orford, 2008). Recently, three-dimensional high resolution maps derived from LiDAR have been used to estimate the cliff face bulk retreat, defined as the volumetric change (measured by differencing successive digital elevation models) divided by the cliff height and the alongshore width of a cliff section (Young and Ashford, 2006a,b).

Cliff top, base, and face change estimates can differ significantly over short time periods. For example, wave action can cause cliff base retreat, but no cliff top change (Fig. 1A). Mid-cliff face erosion can occur without changes to the cliff top or base (Fig. 1B). Alternatively, a cliff top failure may result in significant cliff top recession and no change at the cliff base if the talus is removed by wave action prior to subsequent data collection (Fig. 1C). When talus deposits are incompletely removed between surveys, the cliff base appears to accrete (Fig. 1D, E). Additionally, the cliff base location changes when the beach sand level at the cliff base changes (Fig. 1F, an increase in beach sand level causes retreat of the estimated cliff base location).

Although these estimates will converge over long time periods, short-term, seasonal estimates provide insight into cliff retreat processes (e.g. the relative importance of higher than usual rainfall or waves). Here, changes in the cliff top, cliff base, and cliff face, estimated using nine semi-annual airborne LiDAR surveys spanning four years are compared.

2. Study area

The studied 2.5 km reach of seacliffs in Del Mar, California (Fig. 2B), on average 18 m high with approximately 45° slope, are cut into uplifted marine terraces. The lower cliff consists of the Del Mar Formation, an Eocene sedimentary deposit composed of sandy claystone interbedded with coarse-grained sandstone (Kennedy, 1975). Near the middle of the study area, the Del Mar Formation is overlain by permeable sandy Pleistocene terrace deposits (Fig. 2C). The Del Mar Formation is relatively impermeable, resulting in perched groundwater and sapping at the interface with terrace deposits. The cliff face experiences weathering, desiccation, sheet erosion, and rilling, while the cliff base is subject to wave action. Typical beach width ranges from 30 to 70 m, and fluctuates seasonally with wider beaches in summer. During winter, the eroded beach permits direct wave attack at the cliff base when elevated tides coincide with large
wave events. Subaerial and marine erosional processes result in long-term cliff top retreat rates estimated at 5–20 cm/yr (Benumof and Griggs, 1999; Moore et al., 1999; Young, 2006; Hapke and Reid, 2007). The North County Transit District railroad, currently situated on the cliff top within a few meters of the cliff edge, has been threatened by past cliff failures (Kuhn and Shepard, 1984). Portions of the cliff base stabilized with wooden and concrete seawalls (Fig. 2D) were identified with oblique photographs (California Coastal Records Project, 2008).

Fig. 2. A and B) Study location maps, C) cliff height and composition, D) major seawall locations, and cumulative (4 yr) changes of the cliff (E) face, (F) top, and (G) base versus alongshore location.
The sea cliffs are exposed to waves generated by local winds and distant storms in both hemispheres. During winter, swell from the North Pacific and Gulf of Alaska are most energetic, whereas swell from the South Pacific dominates in summer. Waves reaching southern California cliffs undergo a complex transformation, and “shadows” of the Channel Islands create strong alongshore variations in wave height. The seasonal cycle in the Del Mar region has maximum wave energy in winter. Historical data indicates regional wave heights during the study period (May 2002–March 2006) were typical. San Diego’s semi-arid Mediterranean climate is characterized by dry summers and occasionally wet winters, with 85% of rainfall occurring from November through March. Annual precipitation is dry summers and occasionally wet winters, with 85% of rainfall occurring from November through March. Annual precipitation is

4. Results

4.1. Beach sand levels

Sand level changes measured at the cliff base ranged from 0 to 1.5 m, and were relatively small with an average absolute magnitude of 22 cm. Only 20% of the changes were greater than 35 cm. Over the entire beach face, normal seasonal change is observed (not shown), with elevated sand levels in summer (Aubrey et al., 1980). Interestingly, beach elevation changes at the cliff base were not seasonal. Average sand levels at the cliff base decreased in all time intervals except during the winters of 2003–2004 and 2005–2006. Cobble berms, which are ephemeral features in the region, occasionally build up at the cliff base during winter months and probably contributed to some of the measured beach elevation changes at the cliff base.

4.2. Cliff base changes

Cliff base change is strongly variable alongshore, and change of both signs was observed, both in a given time interval, and cumulatively (Fig. 2C). Alongshore-averaged cliff base changes were negative, except during the summer of 2002 and (especially) the winter of 2004–05 (Fig. 3A). The cumulative (over 4 years) cliff base change in 1-m sections ranged from −4.5 to +4.0 m, with an alongshore average of +12 cm. Cliff base changes were relatively widespread, comprising up to 37% of the study area during a single interval (Fig. 3D). The alongshore average of nonzero changes ranged from −0.5 to +0.7 m over the 8 time intervals (Fig. 3C). The largest change in a 1-m section during any time interval was +7.5 m (accretion), caused by a relatively large and clearly identifiable talus deposit (Fig. 4A).

4.3. Cliff top and cliff face changes

The cumulative cliff top retreat in 1-m sections ranged from 0.0 to −3.8 m (Fig. 2F), with an alongshore average of −14 cm. Changes occurred along less than 8% of the cliff top during any time interval
Cliff face erosion (negative change) was spatially widespread, while cliff face positive and cliff top changes were relatively localized (Fig. 3D). Mean magnitudes of cliff top change (locations of zero change neglected) varied seasonally between −0.5 and −1.5 m, while the mean cliff face measurements were comparatively small (Fig. 3C). Cliff face changes occurred without cliff top or base change when the cliff material was eroded from the central portion of the cliff rather than cliff top or cliff base, and the associated talus was eroded before it could be measured. At all locations with nonzero cliff top retreat, cliff face retreat was also observed.

5. Discussion

5.1. Beach sand levels

The vertical elevation of beach sand at the cliff base limits the portion of the cliff base that can be surveyed, and thus contributes to changes in cliff base horizontal location. Measured horizontal cliff base locations are most affected by sand levels at locations with relatively low cliff base (or talus) slope angles. Although the average beach sand level change magnitude was relatively small and did not result in perceptible cliff base change at most locations, large sand level changes did cause spurious cliff base change measurements in some instances. For example, at one location (where no talus deposition occurred) the sand level was lowered by about 1.0 m, exposing more of the cliff and resulting in a +1.5 m (seaward) change of the cliff base. However, the majority of the observed large magnitude (>1.0 m) cliff base displacements coincided with locations of new talus deposition and talus erosion. The maximum horizontal change caused by sand level change is approximately 2 m, estimated as the maximum change in beach elevation (≈2 m) divided by tan α, where α is equal to the slope at the cliff base (≈45°).

Beach sand level changes can also affect cliff face measurements. For example, if the beach sand level increases prior to talus deposition, the talus volume estimate will include the accreted volume of sand under the talus. This affect is probably relatively small, because most new talus deposits were removed by wave action between surveys (cliff face positive changes ≪ cliff face negative changes, Fig. 4F), and if the talus was not removed only a small portion was generally located on the beach (talus is often deposited on the lower cliff face, Fig. 4A). Furthermore, the average magnitude of beach change was smaller (22 cm) than the vertical change threshold (38 cm). However, these small errors will increase with larger sand level fluctuations. The maximum volume error from fluctuations in sand levels equals approximately the area of talus on the beach multiplied by the maximum expected change in beach sand elevation.

5.2. Cliff base changes

Unlike the cliff top, cliff base location changes are not dominated by retreat (negative change). Cliff base location changes (identified here as the break in slope between the cliff and beach) are a combination of spurious changes resulting from beach sand level changes, talus deposition and removal (Fig. 4A, B), and real cliff base retreat. At much longer time scales (possibly several decades, based on historical erosion rates), cliff base retreat is larger than changes from either talus or beach sand levels, and this method will yield estimates of in situ cliff base erosion.

5.3. Cliff top and cliff face changes

Cliff top retreat was dominated by localized large events, and was the most episodic of the retreat estimates, with a mean magnitude of cumulative cliff top change (−82 cm, locations of zero change neglected) six times greater than mean cumulative change (−14 cm, including all locations). The cliff top and cliff face magnitude-
frequency distributions differ; 50% of cliff top changes were larger than −50 cm, compared with 6% for cliff face change. During most of the study period (an exception is the winter of 2004–2005), negative (erosional) cliff face changes were much more extensive than positive (depositional) changes, indicating that the available wave action was sufficient to erode talus deposits.

Although cliff top and face change differs significantly, there are similarities. For example, mean cumulative cliff face (negative and net) and top changes are correlated ($r^2 > 0.9$), whereas the cumulative cliff base changes are uncorrelated with the top and face (Fig. 3B). The cliff face and cliff top both show seasonality, with relatively more change during winter than summer (Fig. 3B). The cliff face and cliff top both show seasonality, with relatively more change during winter than summer (Fig. 3B). The cliff face and cliff top both show seasonality, with relatively more change during winter than summer (Fig. 3B). The cliff face and cliff top both show seasonality, with relatively more change during winter than summer (Fig. 3B). The cliff face and cliff top both show seasonality, with relatively more change during winter than summer (Fig. 3B). The cliff face and cliff top both show seasonality, with relatively more change during winter than summer (Fig. 3B). The cliff face and cliff top both show seasonality, with relatively more change during winter than summer (Fig. 3B). The cliff face and cliff top both show seasonality, with relatively more change during winter than summer (Fig. 3B). The cliff face and cliff top both show seasonality, with relatively more change during winter than summer (Fig. 3B). The cliff face and cliff top both show seasonality, with relatively more change during winter than summer (Fig. 3B).

### 5.4. Geomorphic perspective

The seasonality of cliff top and cliff face changes reflects the seasonal variation of both wave energy and rainfall, which have greater potential for cliff erosion during the winter months. Our measurements of cliff base changes encompass a variety of processes, some of which can oppose each other during a given time interval. For example during winter months a large landslide deposit causes the cliff base to move seaward, while wave erosion of the cliff base produces landward movement. This type of opposition contributed to the lack of seasonality in observed cliff base changes.

The wet winter of 2004–2005 had a relatively profound affect on the Del Mar seacliffs, with the absolute maximum mean cliff face, cliff top, and cliff base changes all occurring during this winter (Fig. 3A). Rainfall triggered numerous coastal landslides and initiated erosion...
through other subaerial processes ultimately eroding a total volume of about 3500 m³. Available wave action was insufficient to remove the talus, and approximately 1/3 of the total eroded volume (1150 m³) remained as talus at the end of the winter. The remaining talus during this time interval was more than double the volume in all other time intervals combined, and probably temporarily protected in situ cliff material from wave-induced erosion. As these talus deposits are reworked by future wave action, the erosion rates will probably be elevated, because talus is much more easily eroded than in situ cliff material.

Cliff top retreat reduces the overall cliff slope, while cliff base and cliff face erosion (not concentrated at the cliff top) cause overall slope steepening, thus reducing overall cliff stability. During the study period, 50% of both cliff top and cliff face failures were preceded by cliff face erosion at the same location during the previous year. This effect was cumulative over the study period and led to the development of localized erosional hot-spots. At some locations hot-spots persisted for the duration of the study period, with cliff face erosion occurring in 7 of the 8 time intervals. However, cliff face erosion did not necessarily lead to cliff top failure, and only 18% of cliff face erosion locations were followed by a cliff top failure, probably because of the relatively short study time period and the highly episodic nature of cliff top retreat. Over longer time periods, these concepts can be used to develop a seafall erosion hazard index, defined as the difference between cliff top and cliff face erosion. For example, as the cliff face retreat exceeds cliff top retreat, the cliff becomes more unstable, and vice versa.

6. Summary

The three LiDAR-based estimates of cliff retreat, using observations of the cliff top, cliff face, and cliff base, are all limited by the accuracy and density of the observations. Cliff face change estimation is mostly automated, but requires manually deleting erroneous change caused by vegetation or other artifacts (if these areas cannot be removed through automated procedures). Manually digitizing the cliff top and base locations is labor intensive, with substantial errors when there is not a clear slope change between the beach and cliff face, and between the cliff face and cliff top. However, recent advances in automated extraction of cliff top and base positions (i.e. Liu et al., 2009) show promise, and may eliminate the labor intensive manual digitizing methods. Overall, cliff face change estimates were the most informative because all cliff changes, including changes at the cliff top and base, are captured. The cliff face method is also the most automated, and positive and negative changes are easily separated. The cliff top method captures real retreat, but provides only a limited view of cliff evolution. The cliff base method measures changes from basal erosion, but is complicated by a sensitivity to talus and sand levels at the cliff base.

Acknowledgments

LiDAR surveys were sponsored by the U.S. Army Corps of Engineers as part of the Southern California Beach Processes Study. APY received Post-Doctoral Scholar support from the California Department of Boating and Waterways Oceanography Program.
